Robert M. Sulman* (rsulman@centralmethodist.edu), Central Methodist University, Fayette, MO 65248. *Disruption of Symmetry Creates New Symmetries*. Preliminary report.

The quadratic $f(x)=ax^2+bx+c$ ($a>0$) has symmetry about a vertical line. When we divide f by $g(x)=px^2+qx+r$ ($p>0$) the symmetry above is disrupted. However, new symmetries are created and they are examined in this talk. Specifically, the graph of $h=f/g$ will always have a minimum value $y = m$ and a maximum value $y = M$ when $\text{disc}(g)$ is negative and the axes of symmetry of f and g are different. If this is the case, then: (i) $Mm=\text{disc}(f)/\text{disc}(g)$ (ii) $Mm=\beta(f)/\min(g)$, where β is the horizontal asymptote of h and $y=\min(f),y=\min(g)$ are the minimum values of f and g (occurring at each vertex). As a consequence of (ii) we see that if either $\text{graph}(f)$ or $\text{graph}(g)$ are translated horizontally (not to share axis of symmetry), the resulting rational function will have a minimum and maximum value whose product is Mm . That is, the product of extreme values is invariant under horizontal shifts of the numerator and denominator. A look at what this means geometrically and some concrete examples are given. This result is derived solely using methods of Pre-Calculus and is thus accessible to anyone with such background. (Received September 21, 2009)
